Atlantic Coastal Fish Habitat Partnership

Species-Habitat Matrix Project
Summary Report

August 2009
Introduction

Inception of the ACFHP Species-Habitat Matrix

In May 2007, the Atlantic Coastal Fish Habitat Partnership (ACFHP) held its first workshop to discuss the continuing formation of a new partnership for the Atlantic coast under the auspices of the National Fish Habitat Action Plan. At this workshop, the ACFHP Science and Data Working Group was established to provide scientific support to the partnership. In particular, this group was formed to provide the scientific basis for a Conservation Strategic Plan for the ACFHP. With this in mind, partnership representatives Jake Kritzer (Environmental Defense Fund) and Mari-Beth DeLucia (The Nature Conservancy) suggested creating a matrix of species and their habitats to guide the partnership in determining which habitats along the Atlantic coast are used, on a broad regional scale, by the most species.

Following the initial workshop, a subgroup of the Science and Data Working Group convened to design the Matrix. The details of the design and subsequent activities are outlined in the methods section of this report.

Purpose of the ACFHP Species-Habitat Matrix

The primary purpose of the ACFHP Species-Habitat Matrix is to provide a starting point for prioritizing habitats (on both a coastwide and regional basis) in order to focus the protection and restoration efforts of ACFHP. It is a conservation planning tool to evaluate the relative importance of various coastal, estuarine, and freshwater habitats in terms of their value to a number of selected fish and invertebrate species. Specifically, the Matrix evaluates the importance of different habitat types as shelter, nursery, feeding, or spawning areas for each species. The goal is to provide an index of habitat value through this one lens. The Matrix is limited in that it does not consider other important functions of habitat that also benefit each species. Filtering water, processing nutrients, securing sediments, maintaining dissolved oxygen levels, and other ecosystem functions are critical for fishes and invertebrates, but are not considered in the analysis in order to keep the matrix and analyses simple and manageable. However, the additional ecosystem functions of habitats are considered separately in conservation planning in combination with the Matrix results.

Other Uses of the ACFHP Species-Habitat Matrix

While ACFHP designed this Matrix specifically to help the Partnership prioritize habitats, there are many other potential uses for this work in the future. The Matrix could assist natural resources agencies, non-governmental organizations, or other groups in identifying monitoring or research focuses, identifying data gaps, or assessment work. In addition, a comprehensive database for Atlantic coast species could be compiled from the associated references. Please note that any use of the Species-Habitat Matrix should keep in mind the Qualifiers and Exclusions noted in the following section.
**Qualifiers and Exclusions**

- The Matrix is not a comprehensive index of all species or habitats along the Atlantic coast.
- This Matrix will not assess the amount, condition, or vulnerability of habitat types.
- The Matrix does not begin to cover the full range of ecosystem services associated with habitats, and their importance to the health and sustainability of the ecosystem as a whole. It will not evaluate habitats in terms of ecological functions, such as buffering coastal areas, water filtration, nutrient processing, trapping and stabilizing sediments, and so on.
- A representative grouping of species was chosen for each region, in an attempt to cover most functional groups within the ecosystems of that region. The species lists include mostly finfish and selected motile invertebrates. Although bivalves are of tremendous ecological and economic value, most of the major species are included as habitat categories, and therefore are not included as species as well. In this way, they have heightened importance given that the focus of ACFHP is habitat protection and restoration.
- The Matrix does not consider the natural rarity of a habitat type, current habitat trends, or comparative use with information obtained from the Assessment of Existing Information (a separate ACFHP project).
- The use of pelagic habitats was not considered as part of this Matrix. This Matrix should only be used to evaluate utilization of physical habitat, not use of the water column. Water quality should be acknowledged as an important consideration for all species included in this Matrix.
- There may be habitats that are important for some species that do not fit readily into the scheme provided in this Matrix. While we acknowledge that not every habitat is included, we think that most habitats for most species are covered.
- Differentiations between life history stages for each species should be based upon the generally accepted distinctions provided in the literature for that species.

**Methods**

**Regional Breakdown and Regional Leads**

This Matrix was completed for four regions of the Atlantic coast (Figure 1). Each region had a regional lead that was responsible for finding volunteers to complete the Matrix for the various species included in that region. Regions and regional leads are as follows: New England (Cape Cod north to Canada), Leads- Lou Chiarella, Kim Damon-Randall, and Vin Malkoski; Mid-Atlantic (Cape Cod to Cape Hatteras), Leads- Bill Shadel, Marek Topolski, and Caroly Shumway; South Atlantic (Cape Hatteras to Cape Canaveral), Lead- Kay Davy; and South Florida (south of Cape Canaveral), Leads- Kent Smith, Eddie Matheson, and Jeff Beal. A complete list of Matrix contributors can be found in Appendix A of this report.
Figure 1. ACFHP Regions

Discussion of Spreadsheet and Determination of Categories

The ACFHP Species-Habitat Matrix exists in a series of Microsoft Excel spreadsheets. The left-hand columns consist of 26 habitat types nested within seven habitat categories (see Habitat Characterizations below for more detail). The species are listed across the top of each row, with four columns included per species (one for each life stage: eggs/larvae, juveniles/YOY, adults, and spawning adults). At each intersection of a habitat type and species’ life stage is a “score” reflecting the species’ use of the habitat type at that life stage. By summing these scores across a habitat type,
an index of the habitat’s value for a collective group of species can be generated. An example of a completed matrix for red drum is illustrated in Figure 2 below.

Additionally, each region had its own list of species covering the major functional groups found in that region. An attempt was made to cover a range of trophic levels (e.g., from bay anchovy to oyster toadfish to various coastal sharks), as well as to include species of commercial and recreational importance. Strictly freshwater species are not included within the focus of ACFHP, and therefore are not present in the Matrix.

Each species could be scored for one, two, three, or four regions, depending on its relative prevalence in each region. Therefore, some species, such as American eel, were scored for all regions, whereas a species like Caribbean reef squid was only scored for South Florida. The species list for each region was determined by a group of experts from that region. Ultimately, 36 species were scored for New England, 55 for Mid-Atlantic, 62 for South Atlantic, and 62 for South Florida (see Appendix B for complete lists). The total number of species included in the ACFHP Species-Habitat Matrix across all regions was 131.

**Figure 2. Example of Red Drum Species-Habitat Matrix**

*Habitat Characterizations (see Appendix C for more detailed descriptions)*

**Marine and Estuarine Shellfish Beds**
- Oyster reef
- Scallop beds
- Hard clam beds
- Dead shell accumulations

**Other Sessile Fauna**
- Primary coral reef architecture
- Patch reef, soft corals, or anemones amidst soft sediment
- Live rock (inert hard bottom with hydroids, bryozoans, tube worms, sponges, etc.)

**Macroalgae**
- *Fucus* sp., *Laminaria* sp., *Ulva lactuca* mats, *Sargassum* sp., and other drift algae

**Submerged Aquatic Vegetation (SAV)**
- Tidal fresh and oligohaline spp.
- Mesohaline and polyhaline spp.

**Tidal Vegetation**
- Saltwater marsh
- Brackish marsh
- Tidal freshwater marshes
- Mangrove
Coastal Inert Substrate
- Loose fine bottom
- Loose coarse bottom
- Firm hard bottom
- Structured sand habitat

Riverine
- Higher gradient headwater tributaries
- Lower gradient tributaries
- Higher gradient large mainstem river
- Lower gradient large mainstem river
- Low order coastal streams
- Non-tidal freshwater mussel beds
- Coastal headwater ponds
- Non-tidal freshwater marshes

Instructions and Scoring

Each regional matrix was distributed to the regional leads, who, in turn, distributed it to the other contributors to fill out. The following instructions, scoring scheme, and format for references were sent along with the Microsoft Excel spreadsheets in an attempt to standardize the evaluations:

Overall Summary

Attached you will find the ACFHP Species-Habitat Matrix Excel workbook. Note that the list of species across the top of the table divides into four major life history stages for each species. Down the left hand side of the table, you will notice a list of habitat types. ACFHP wants to score, or evaluate, the relative importance of each specific habitat type to a given life history stage for each species. This “Matrix” will help us in identifying key species-habitat relationships for the Partnership’s efforts.

Each species’ use of a habitat will be scored using an algorithm that will ultimately aid in identifying those habitats types and categories which provide the greatest amount of benefit for multiple species. Species’ use of specific habitats will be evaluated on a five score basis: Very High, High, Medium, Low, or Unknown. Your job will be to fill in the cells of each life history stage with a VH, H, M, L, or U. The scoring system (i.e., what each letter stands for) is described below. Ultimately, we will be able to replace these letters and test several numeric scoring methods.

Regional Guidelines

- There are four regions within ACFHP:
  - New England (Canadian border to Cape Cod)
  - Mid-Atlantic (Cape Cod to Cape Hatteras)
  - South Atlantic (Cape Hatteras to Cape Canaveral)
  - South Florida (Cape Canaveral south)

- Each region will submit ONE matrix. It is up to the regional leads to compile and combine results from their team members.
- Team members must cite their findings, and multiple citations per species are strongly encouraged wherever possible.

- Multiple team members working on the same species would be ideal, but one person per species is acceptable.

**General Guidelines**

- Use the best available literature – scientific journal articles, agency reports, ASMFC documents, species reviews, fishery management plans, federal reports, etc. – to help you identify and score important habitats for the species within your region. You can also cite expert opinion, but please make sure you document it well (include full name, contact info, and agency or organization).

- The east-west limits of ACFHP range from headwaters that are, or once were, accessible from the sea to the three-mile state jurisdictional limit. If a species’ life stage primarily occurs beyond the three-mile limit (e.g., “Spawning Adults” for American eel), that life stage should not be included in the Matrix. Future expansions of the Matrix might range further offshore, but initially our focus is the headwater to three-mile extent of ACFHP.

- Document your references for each rank or species-habitat relationship in a separate Microsoft Word (or compatible) document, and record any comments you may have. See example format at end of this document.

- Only use the “Spawning Adults” column if habitat use by adults is fundamentally different between spawning and non-spawning periods (e.g., diadromous species). If it is not, only complete the “Adults” column and grey out the “Spawning Adults” column.

- “YOY” and “Juvenile” have been combined into one category because available information for different species is defined differently, with information for some species specific to young of the year and information for other species applicable more broadly to immature fish. This column combines these young life stages.

- If the species does not use the habitat for a specific life history stage, leave the corresponding cell blank. This means that blank cells have a meaning, so if the habitat use is actually unknown, be sure to indicate that with a U.

- For any species that are not found in your region, please make their columns gray so that we know those species were not considered.

- Do not combine scoring letters (e.g., H-M). Use the literature and your best professional judgment if you cannot decide between two scores. Document any additional thoughts or rationale in your accompanying documentation.
Scoring Scheme

- **Very High (VH):** Essential contributor; the given life history stage for this species cannot be completed without enough high quality occurrences of this habitat type.

- **High (H):** Important contributor to the success of this life history stage; can be occasionally substituted by use of one or more additional habitat types, but the majority of this life history stage takes place in this habitat type.

- **Moderate (M):** Moderate contributor; one of many habitat types which contribute to the success of this species life history stage; substitutions with other habitat types are frequently found; not a major contributor of success but one of many.

- **Low (L):** Not an essential contributor, used incidentally; other habitat types play a much greater role in success for this life history stage.

- **Unknown (U):** If something is truly an unknown (to science) you can put a U. Be sure to include any questions or issues which might be related to the issue in your accompanying documentation.

Example Format for References and Comments

Name:  Jane Doe  
ACFHP Region:  South Atlantic  
Assigned Species:  American eel, American shad, etc.

Reference(s):

**American eel (general)**

**American eel (eggs-larvae)**

**American eel (comments or notes)**

[Note: When a reference is specific to a life history stage please note here.]

Although American eels spawn in the Sargasso Sea, exact location, depth, etc. is still unknown.

**American shad**  (NEW PAGE)

Repeat format above
Matrix Review and Completion

Once the original contributors from each region completed a scored matrix for each species, the coastwide matrix leads (Mari-Beth DeLucia, Emily Greene, Jake Kritzer, and Jessie Thomas-Blate) compared the scores for each species among regions. The Matrix leads determined that all species had some minor differences, and most species had some major differences in their scoring among regions. The group was not sure if this was a reflection of actual regional differences or subjective interpretation of the literature.

Consequently, a Species-Habitat Matrix Review Work Group of experts was formed (see Appendix A for a list of members). This work group met on February 19 and 20, 2009, in Raleigh, North Carolina, to discuss these regional differences and review each completed matrix based on literature cited and personal knowledge of the species. At this meeting, differences among regions were discussed and altered as appropriate. Following the meeting, the revised matrices were distributed to the original contributors for their final review.

A series of additional reviews occurred via conference calls with a subset of workgroup experts. For species for which the workgroup members did not feel qualified to render a score, independent reviews were utilized (see Appendix A for a list of these individuals).

Analysis

After completion and review of the Matrix, rankings (i.e., L, M, H, and VH) were converted to numerical scores using the “4-3.5-2-1” System in which Very High = 4; High = 3.5; Moderate = 2; and Low = 1. Rankings of “U” (unknown) were not part of the analysis, but were recorded as knowledge gaps. This scoring/ranking system was modified by the Matrix developers from The Nature Conservancy’s 5-S Planning Framework (TNC 2000). The non-linear numeric relationship reflects that habitats ranked Very High or High represent important or essential habitats to a specific life stage, and should receive proportionally higher numerical scores than those habitats that are only used occasionally or in conjunction with many other habitats by a species. However, this also allows for a variety of analyses to be run on the results that can answer questions such as, “what habitat type received the most scores regardless of ranking?”

Analyses were run on both the broader Habitat Categories (i.e., Riverine), as well as the more specific Habitat Types (i.e., low order coastal streams). The results of this analysis can be found, ranked according to the five highest scoring habitats for each metric, in region-specific summary tables in Appendix D.
Matrix Analysis Metrics (assessed by region):

**Habitat Category with Highest Overall Score:** Sum of scores across all fish species and life stages for all habitat types within a habitat category.

**Habitat Type with Highest Overall Score:** Sum of scores across all fish species and life stages within a habitat type.

**Habitat Type with Highest Nursery Score:** Sum of scores across all fish species within a habitat type, for the juvenile/young-of-year life stage.

**Habitat Type with Highest number of H/VH Scores:** Count of boxes valued with H and VH scores, across all fish species and life stages within a habitat type.

**Habitat Type with Highest number of L/M Scores:** Count of boxes valued with L and M scores, across all fish species and life stages within a habitat type.

**Habitat Type with Highest # of Boxes with Any Score:** Count of boxes valued with L, M, H, and VH scores, across all fish species and life stages within a habitat type.

**Ratio of H/VH to L/M Scores:** Count of H and VH scores (as described above) divided by the count of L and M scores (as described above).

---

**Results and Discussion**

**New England**

_Coastal Inert Substrate_ was the highest scoring habitat category in the New England region. Of course, the ranking of the categories are clearly not independent of the number of habitat types within each. Still, four habitat types within the _Coastal Inert Substrate_ category were among the five highest scoring of all habitat types, suggesting that high category ranking is not due solely to the number of habitat types, but also reflects their individual importance.

_Loose Fine Bottom_ had the highest overall score among habitat types, and was also the highest ranked type for four of the five remaining analyses (i.e., highest juvenile/YOY score; highest number of H/VH scores; highest number of M/L scores; highest number of any score). This result is perhaps not surprising, given that _Loose Fine Bottom_ is likely to be the most abundant habitat type, and therefore is likely to be used by the greatest number of species. If this is the case, the results highlight the fact that, although the Matrix is not designed to provide insights into habitat rarity, condition, or other features, these characteristics have an influence on habitat use and therefore on the Matrix results.

The only scoring system for which _Loose Fine Bottom_ was not the top-ranked habitat was the ratio of H/VH to L/M scores. The purpose of this metric is to identify those habitat types that tend to be
used mostly by habitat specialists, with less use by habitat generalists or less opportunistic use. The
top five habitat types highlighted by this metric all fall within the Riverine category, a result that was
influenced in part by the diadromous species in the Matrix. For diadromous species, Riverine habitats
are of critical importance, but these habitats are not always of direct use to purely marine or
estuarine species. However, the relative score of Riverine habitat meant that, not only did this
category have the highest proportion of H and VH scores, but also that its aggregate score made it
the second ranked category.

Submerged Aquatic Vegetation was the third highest ranked category in New England, a notable result
given that the category only contains two habitat types. The importance of this category was driven
largely by the Mesobaline-Polyhaline Species habitat type, which was one of the top five habitat types
according to raw score, and one of the top types in four of the five other metrics considered. Like
Loose Fine Bottom, the Mesobaline-Polyhaline Species habitat type only failed to rank by the ratio of
H/VH to L/M scores, again due to the dominance of riverine habitat types. The highest position
for Mesobaline-Polyhaline Species occurred when the scores were restricted to juvenile and YOY life
stages, where it ranked second, underscoring the importance of this habitat type as a nursery ground.

Mid-Atlantic

The results for the Mid-Atlantic region were very similar to those for New England. Coastal Inert
Substrate was the highest ranking category, and Loose Fine Bottom was the highest ranking habitat type
by all metrics except for the ratio of H/VH to L/M scores. There again, the Riverine habitat types
-dominated. Submerged Aquatic Vegetation also scored fairly high, according to several metrics driven
by the importance of Mesobaline-Polyhaline Species much more than by Tidal Freshwater and Oligobaline
Species.

The similarity in the results between these two regions is no doubt due to a similar distribution of
many important determinants of species and habitat abundance and distribution, as well as habitat
use by species. These determinants may be either natural variables (e.g., oceanography, geology,
hydrology, and climate) or anthropogenic (e.g., population density, urbanization, and agricultural
patterns). These factors do not change abruptly at Cape Cod, and maintain a high degree of
similarity between the two regions.

South Atlantic

Although the same factors that likely lead to the similarities between New England and the Mid-
Atlantic also continue through the South Atlantic, the results show less similarity. This is driven in
part by much larger differences in the suite of species considered in the South Atlantic compared to
the more northern regions. The South Atlantic shares many tropical and sub-tropical species with
the South Florida region, and the addition of those species has a pronounced effect on the results.
The sheer number of new species changes the relative weight of others, and their ecology changes
patterns of habitat use.

For example, the Riverine category, and the habitat types within it, does not rank as high in the South
Atlantic as it does in the Mid-Atlantic and New England. In the South Atlantic, some diadromous
species are no longer present (e.g., Atlantic salmon, sea-run brook trout, sea lamprey, and rainbow
smelt), and those that remain are an even smaller proportion of the overall species list due to the new species considered. Also, Oyster Reef and Live Rock appear as more important habitat types in the South Atlantic by several metrics, likely reflecting the beginnings of the reef fish fauna that becomes truly dominant in South Florida.

Additionally, even along generally continuous gradients, it is possible to cross thresholds that lead to large ecological changes. One notable result in the South Atlantic is the greater importance of the Tidal Vegetation category and the Saltwater/Brackish Marsh type within it. Moving south along the Atlantic coast, the increases in elevation moving inland become much more gradual, resulting in more extensive marsh systems that allow for greater use by more species. Coastal Inert Substrate (especially Loose Fine Bottom) still ranks highly in the South Atlantic, but is not as dominant as it is in the northern regions.

South Florida

The arising dominance of reef fishes in the southern tropical and sub-tropical range of the Atlantic coast is clear in the South Florida region. The Other Sessile Fauna category scored highest; Patch Reef, Soft Corals, and Anemones was the highest scoring habitat type, and the Primary Coral Reef Architecture habitat type ranked highest in two of the five other metrics. The sheer number of species in the South Florida matrix, and the high ranks of the sessile fauna habitats within the region, perhaps suggest that these habitats need to be broken into more precise habitat types within this region than is required elsewhere in order to refine conservation planning.

Live Rock and Firm Hard Bottom also rank much higher than in any other region. Firm Hard Bottom is not part of the Other Sessile Fauna category, but has many of the same structural and functional attributes. In fact, unlike any of the other three regions, the results for Coastal Inert Substrate in South Florida are driven as much or more by the importance of Firm Bottom as they are by Loose Fine Bottom, which is the dominant type within the category elsewhere.

Only by the nursery habitat metric (i.e., highest juvenile/YOY score) does another habitat type rank highest, with Mesohaline-Polyhaline SAV in the top spot. Of course, many of the fishes that spend most of their lives on coral reefs also use SAV at young life stages.

Future directions

The results of this project will guide conservation strategic planning for ACFHP, in conjunction with other scientific projects. However, the Matrix effort produced an extensive database that may be used to address other ecological and management questions than those considered here. Those additional analyses will continue to help inform the work of ACFHP as the partnership further develops. At present, the initial results have provided a great deal of information on the importance of the various habitat types in each region, and shaped our planning to date.

As noted earlier, the Matrix does not consider all of the ecosystem functions provided by habitats, only their value as living space. A parallel planning tool would look at the full range of ecosystem services provided by a habitat type to help inform decision-making. For example, in all regions, Shellfish Beds generally scored very low. However, it is well known that shellfish are important in
maintaining water quality, and therefore are important for other invertebrates and fishes, even if those species do not live directly on or among shellfish. Furthermore, the ACFHP Assessment of Existing Information is an example of another tool that provides more explicit information on habitat status and trends in each region.

In the future, the Matrix will be updated based on new information that emerges in the fish ecology and restoration literature. Matrix updates will also include information gathered from monitoring programs implemented under ACFHP-sponsored restoration projects. Through this process, the ACFHP Species-Habitat Matrix will identify knowledge gaps and set conservation priorities. In turn, new research to address priorities will feed back into the Matrix to make this evaluation more robust and improve our understanding of species-habitat relationships in future versions.

**References**

With more than 100 species included in the matrix, and multiple references used to rank habitat use by each, several hundred scientific papers, reports, books, management plans, and other sources were used to complete this analysis. Because this volume of literature is too great to list in full in this summary report, we are in the process of creating a searchable online database of the full reference list, as well as the notes for each species describing the scores given. Please contact the ACFHP Coordinator with questions about references and notes, and for updates on development of the online database.

### Appendix B: List of Species Included for Each Region

#### New England

- Alewife
- American eel
- American lobster
- American shad
- Atlantic cod
- Atlantic herring
- Atlantic mackerel
- Atlantic menhaden
- Atlantic salmon
- Atlantic silverside
- Atlantic sturgeon
- Atlantic tomcod
- Bay anchovy
- Black sea bass
- Blue crab
- Blueback herring
- Bluefish
- Butterfish

- Cunner
- Horseshoe crab
- Little skate
- Loligo squid
- Northern shrimp
- Ocean pout
- Oyster toadfish
- Pollock
- Rainbow smelt
- Red hake
- Sand lance
- Sea lamprey
- Sea-run brook trout
- Shortnose sturgeon
- Spiny dogfish
- Tautog
- Windowpane flounder
- Winter flounder

#### Mid-Atlantic

- Alewife
- American eel
- American lobster
- American shad
- Atlantic cod
- Atlantic croaker
- Atlantic herring
- Atlantic mackerel
- Atlantic menhaden
- Atlantic needlefish
- Atlantic salmon
- Atlantic silverside
- Atlantic sturgeon
- Atlantic tomcod
- Bay anchovy

Appendix C: Habitat Descriptions

Marine and Estuarine Shellfish Beds

Oyster reef
Structures formed by the Eastern oyster (*Crassostrea virginica*) that provide the dominant structural component of the benthos, and whose accumulated mass provides significant vertical relief (> 0.5 m).

Scallop beds
Areas of dense aggregations of scallops on the ocean floor. Common Atlantic coast species include: 1) the large Atlantic sea scallop (*Placopecten magellanicus*), which ranges from Newfoundland to North Carolina; 2) the medium-sized Atlantic calico scallop (*Argopecten gibbus*), which is found in waters south of Delaware; and 3) the bay scallop (*Argopecten irradians*), which occurs from Cape Cod to Florida, as well as in the Gulf of Mexico.

Hard clam beds
Dense aggregations of the hard clam (*Mercenaria mercenaria*) found in the subtidal regions of bays and estuaries to approximately 15 meters in depth. Clams are generally found in mud flats and firm bottom areas consisting of sand or shell fragments.

Dead shell accumulations
Shells of dead mollusks sometimes accumulate in sufficient quantities to provide important habitat. Accumulations of Eastern oyster shells are a common feature in the intertidal zone of many southern estuaries.

Other Sessile Fauna

Primary coral reef architecture
Reef-building corals are of the order Scleractinia, in the class Anthozoa, of the phylum Cnidaria. Coral accumulations are restricted to warmer water regions, where the average monthly temperature exceeds 18°C (64°F) throughout the year. Through symbiosis with unicellular algae, reef-building corals are the source of primary production in reef communities.

Patch reef, soft corals, or anemones amidst soft sediment
A patch reef is an isolated, often circular, coral reef usually found within a lagoon or embayment. Soft corals are species of the anthozoan order Aleyonacea, of the subclass Octocorallia. In contrast to the hard or stony corals, most soft corals do not possess a massive external skeleton (examples: sea pens and sea fans). Anemones are cnidarians of the class Anthozoa, and possesses a flexible cylindrical body and a central mouth surrounded by tentacles found in soft sediments.
Live rock (inert hard bottom with hydroids, bryozoans, tube worms, sponges, etc.)
Calcereous rock that is removed from the vicinity of a coral reef with some of the life forms still living on it. These may include bacteria, coralline algae, sponges, worms, crustaceans, and other invertebrates.

Macroalgae
Large marine multi-cellular macroscopic algae (seaweeds). There are three types of macroalgae: green, brown, and red. Examples of macroalgae species found along the Atlantic coast:

Chlorophyta (green algae)
Ulva lactuca, sea lettuce

Phaeophyta (brown algae)
Fucus vesiculosus, bladderwrack; Laminaria spp.; Sargassum spp.

Rhodophyta (red algae)
Chondrus crispus, Irish moss

SAV
Submerged aquatic vegetation (SAV) refers to rooted, vascular plants that live below the water surface in large meadows or small patches in coastal and estuarine waters. SAV can be further classified by the range of salinity of the waters in which they are found.

Tidal fresh and oligohaline species
Generally found in areas where salinity ranges from 0.5 to 5.0 ppt. Examples include:
Vallisneria americana, wild celery
Ceratophyllum demersum, coontail

Mesohaline and polyhaline species
Generally found in areas where salinity ranges from 5.0 ppt up to 30 ppt. Examples include:
Zostera marina, eelgrass
Ruppia maritime, widgeon grass

Tidal Vegetation
Saltwater and brackish marsh
Saltmarsh is a type of marsh that is a transitional intertidal between land and brackish water. The low marsh zone floods twice daily, while the high marsh floods only during storms and unusually high tides. Smooth cordgrass (Spartina alterniflora) dominates the regularly flooded low marsh along much of the Atlantic coast. In addition, salt meadow cordgrass (Spartina patens), saltgrass (Distichlis spicata), and needle rush (Juncus sp.) species comprise much of the vegetative community of the mid to upper saltmarsh and brackish marsh.
**Tidal freshwater marsh**

Tidal freshwater marsh occurs where the average annual salinity is below 0.5 ppt. It is found along free-flowing coastal rivers, and is influenced twice daily by the incoming tides. Tidal freshwater marsh can be located just upstream of the salt front, where the river essentially backs up as it meets resistance from high tides. Tidal freshwater marsh is characterized by salt intolerant plant species. Plant species often found in freshwater tidal marshes include: giant cordgrass (*Spartina cynosuroides*), sawgrass (*Cladium jamaicense*), cattails (*Typha* sp.), arrow arum (*Peltandra virginica*), pickerelweed (*Pontederia cordata*), blue flag (*Iris virginica*), and softstem bulrush (*Scirpus validus*).

**Mangrove**

The mangrove ecological community includes four tree species collectively called mangroves. This swamp system occurs along intertidal and supratidal shorelines in southern Florida. The four species found in Florida mangrove swamps are:

- *Rhizophora mangle*, red mangrove
- *Avicennia germinans*, black mangrove
- *Laguncularia racemosa*, white mangrove
- *Conocarpus erectus*, buttonwood

**Coastal Inert Substrate**

**Loose fine bottom (mud, silt, sand)**

Submerged underwater bottom habitat in estuaries and oceans where the dominate-sized sediment type is mud, silt, or sand.

**Loose coarse bottom (gravel to cobble)**

Submerged underwater bottom habitat in estuaries and oceans where the dominant sediment type ranges from gravel to cobble.

**Firm hard bottom (boulders to embedded rock)**

Submerged underwater bottom habitat in estuaries and oceans where embedded rock or boulders is the dominate sediment type.

**Structured sand habitat (shoals, capes, offshore bars, etc.)**

Linear, narrow sand features that develop where a stream or ocean current promotes deposition of sand.

**Riverine**

**Higher gradient headwater tributaries**

Streams in which the dominant substrate is comprised of gravel and cobble. The stream slope is greater than 2.0%. This characterization includes 1st to 3rd order streams.
Lower gradient tributaries
Streams in which the dominant substrate is comprised of sand, gravel, and small cobble. The stream slope is between 0.51% and 2.0%. This characterization includes 1st to 3rd order streams.

Higher gradient large mainstem river
Rivers in which the dominant substrate is sand, gravel, and cobble. The stream slope is between 0.51% and 2.0%. This characterization includes 4th order rivers and above.

Lower gradient large mainstem river
Rivers in which the dominant substrate is fine sediments (silt-mud-sand). The stream slope is between 0.51% and 2.0%. This characterization includes 4th order rivers and above.

Low order coastal streams
Generally low gradient 0% to 0.05% in slope. This characterization includes 1st to 3rd order streams located along the coast.

Non-tidal freshwater mussel beds
Freshwater mussel beds, located above tidal influence.

Coastal headwater pond
A pond connected to coastal streams and rivers, generally located near the headwaters.

Non-tidal freshwater marsh
A marsh that occurs in the non-tidal section along a river. The main feature of a freshwater marsh is its openness, with only low-growing or "emergent" plants. It may include grasses, rushes, reeds, typhas, sedges, and other herbaceous plants (possibly with low-growing woody plants) in a context of shallow water.
### Appendix D: Summary Results of the Species-Habitat Matrix by Region

(Note: The habitat category in which a habitat type falls is shown in brackets. Raw analysis scores are shown in parentheses.)
